Description

Field of the Invention

[0001] This invention relates to radio-frequency identification systems which operate with sequential power/read functions, and, more particularly, to an identification system as defined in the precharacterizing portion of claim 1 and to a remote sensor system as defined in the precharacterizing portion of claim 4 as well as a method of interrogation in such systems.

Background of the Invention

[0002] Radio-frequency identification systems with interrogator sequential power/read functions, operate over a large dynamic range with regard to field strength levels. This phenomena stems from the fact that the largest required reading range of any given read area defines the power level in conjunction with the predetermined time window. If an RF-ID system is designed for maximum range, the close-proximity field strength is very high for the transponders nearest the interrogator. In such cases, transponders may be heated up by the over-voltage protection circuit which is absorbing excessive power in near field conditions. The second negative effect is that most of the charge-up pulse is wasted for the closest transponders. If, for example, a power pulse must be 50 milliseconds in length to charge the furthest transponder, but the closest transponder requires only 5 milliseconds to obtain sufficient energy to return a reply, the other 49.5 milliseconds of the power pulse is wasted on the closest transponders.

[0003] The over-charging problem is especially disadvantageous in temperature sensor applications. In such applications, an accurate temperature measurement may not be obtainable because the transponder eventually dissipates the extra power pulse energy in the surrounding area of the sensor, which is typically in the temperature measurement vicinity. Over-charging can cause the temperature of the transponder to rise anywhere from 20-80 C, depending upon the required reading range and/or the transponders distance from the interrogator, thereby causing enormous errors in the temperature measurement readings.

[0004] The duration of the interrogation power pulse, thus the energy consumption and heating-up of the transponder, as well as the energy consumption of the interrogation unit can be optimized by the proposed invention.

[0005] EP-A-0 301 127 discloses an identification/remote sensor system comprising a transponder for receiving pulses of energy and then transmitting a response signal and interrogator for transmitting a series of said interrogation pulses, said interrogator further including a receiver for monitoring said response signal.

[0006] EP-A-0 442 390 discloses a batteryless transponder which comprises a resonant circuit which can be

stimulated to oscillate by interrogation pulses, an energy storage capacitor which receives energy from the stimulated resonant circuit and a voltage limiting means for limiting the voltage at the energy storage capacitor. If the voltage exceeds a desired value the voltage limiting means switches via a transistor a further capacitor in series to the resonant circuit such that the resonance frequency of the resonant circuit is shifted. As a result the charging of the energy storage element is interrupted and an undesired dissipation of excess energy can be avoided.

Summary of the Invention

[0007] Since the distance from the interrogator to the transponder cannot be controlled in many RF-ID applications, a time or power control over the interrogation pulse is provided to eliminate transponder heat-up. According to one aspect of the invention, an identification system comprising the features of the characterizing portion of claim 1 is provided. The RF_ID system according to a preferred embodiment of this invention transmits a narrow interrogation pulse, for example of 5 msec duration and then monitors for an even shorter duration, for example 1 msec, for a transponders response signal. The monitoring duration is maintained a minimum to create the most efficient charge-up system. Upon the absence of the transponders response signal, the interrogator increases the interrogation pulse duration in steps, until the receiver in the interrogator detects a response signal. A response signal indicates that the transponder has received enough power from the interrogation signal, represented as a voltage stored on a capacitor located in the transponder. This system can be supported by transponders which have no discharge function, to allow the transponders to achieve the final charge-up voltage level with a series of combined short duration power pulses, or by transponders which have discharge functions and which must wait for an adequate duration interrogation pulse to receive enough voltage.

[0008] Moreover, according to one embodiment, when more than one transponder is within an interrogation read range, after a transponder has sent a response message back to the interrogator, that transponder is inactivated for a predetermined amount of time to allow the rest of the transponders in the read range to respond to an interrogation pulse.

[0009] According to a further aspect of the invention, a remote sensor system comprising the features of the characterizing portion of claim 4 is provided.

[0010] According to a still further aspect of the invention, a method of interrogation as defined in claim 7 is provided.

Detailed Description of the Preferred Embodiments

[0019] A block diagram of an interrogator is shown in Figure 1. According to a first preferred embodiment, an oscillator 10 of the interrogator 9, commanded by a microprocessor not shown, sends a signal through a variable amplifier 12 to a coupler 14, where the amplified interrogation signal resonates the parallel resonant combination 16 and is transmitted via the antenna 18. The first interrogation signal transmitted is a short power pulse, for example, 5 milliseconds, which is shorter in pulse duration than would be required to power up the most distant transponder. The receiver 20 of the interrogator 9 then listens for a short, predetermined time period, for example, 1 millisecond, for a transponders response signal. If the receiver 20 does not detect a response during the predetermined listening time period, it sends a control signal to the Pulse Width Control Circuitry 21. According to one embodiment, the Pulse Width Control Circuitry 21 includes a data control circuit 22 which receives the control signal from receiver 20, and in turn sends a signal to the time duration control circuit 24 to increase the duration of the interrogation pulse. The interrogator 9 continues a cycle of sending successively longer duration interrogation pulses and monitoring for a transponders response until the receiver 20 in the interrogator 9 detects the presence of a transponders response signal, thereby signifying an adequate charge-up power level in the transponder.

[0020] In either embodiment, the interrogation pulse is received by antenna 26 of the resonant circuit 28 which resonates with the interrogation signal frequency in the transponder 25 shown in Figure 2. The interrogation pulse is rectified by the diode 30 and the voltage stored in energy storage element 32. Circuit element 38 generates the transponder response signal in response to the termination of the interrogation pulse and a voltage level representative of a predetermined amount of power received from the interrogation pulse signal. The termination of the interrogation pulse is detected in the transponder by an RF threshold detector, which is not shown, when the amplitude of the RF oscillation at the resonant circuit 28 has dropped below a predetermined level. Therefore, for transponders 25 with no discharge function, the interrogation pulses are received, rectified and stored such that, if the received pulses do not translate into enough power to enable a response, the transponder 25 substantially maintains the current voltage level and waits for another interrogation pulse. On the other hand, for a transponder 25 with a discharge function, the interrogation pulse is received, rectified and stored such that, if the received pulse does not translate into enough voltage to enable a response, the transponder 25 is discharged and must wait for a longer duration pulse. The difference between charging a transponder 25 with a discharge function and charging a transponder 25 without a discharge function, located the same distance from an interrogator 9, is that the transponder 25 with no discharge function can charge-up to the required voltage with a series of short duration, or low amplitude pulses and the transponder 25 with a discharge function must wait for a longer duration, or higher amplitude interrogation pulse.

[0021] As an illustration of the variable duration interrogation pulse preferred embodiment, the task of locating a single transponder which has a discharge function is addressed. An interrogation pulse of short duration is transmitted initially from the antenna 18 of interrogator 9. Then, receiver 20 listens for a predetermined time period, much shorter than the duration of the interrogation pulse, and upon the absence of a transponders response signal, Pulse Width Control Circuit 24 increases the duration of the interrogation pulse. Although the transponder 25 has not responded, signifying storage of an insufficient amount of interrogation signal energy, the transponder 25 may have stored some energy from the interrogation signal, simply not enough to transmit a response signal. However, because the transponder 25 has a discharge function, as soon as the transponder acknowledges that the interrogation signal has terminated and there is an inadequate amount of energy stored, transponder 25 discharges. Therefore, to charge-up transponder 25, an interrogation pulse of the same duration as the first interrogation pulse would not suffice. The transmission of a longer duration interrogation pulse, as transmitted by the interrogator 9 of Figure 1 would be necessary. Thus, the interrogator 9 continues

to send longer and longer duration interrogation pulses until the interrogator detects the presence of a transponders response signal. In this way, the transponder is charged to the required voltage without heating up with excess interrogation signal energy. In another embodiment of the invention, the transponder 25 does not have a discharge function. Therefore, a series of interrogation pulses having the same duration may also charge-up the transponder 25 to the required voltage also without causing the transponder 25 to heat up with excess interrogation signal energy.

[0022] One of the greatest advantages offered by the interrogator transmitting a series of short duration, lower power interrogation pulses versus very long duration, very high power interrogation pulses is realized in a remote temperature measurement system. Transponders 25 which have temperature measurement sensors, are prone to inaccurate temperature readings in a standard RF-ID system which continually transmits an interrogation pulse of adequate duration to charge-up the furthest transponder. By transmitting a minimum duration interrogation signal, followed by successively longer interrogation pulses, transponders with temperature sensors can achieve more accurate temperature measurements. For example, in a prior-art remote temperature sensor system, a transponder receives, stores and rectifies the interrogation signal and upon a detected decrease in the power level of the interrogation signal and in response to a voltage level representative of a predetermined amount of power received from the interrogation pulse signal, makes a temperature measurement and transmits a transponder response signal indicative of the temperature measurement. In addition, if the interrogation pulse is of longer duration than necessary to charge the transponder to the predetermined voltage, the remainder of the interrogation pulse is received, rectified and dissipated as heat, as shown in Figure 3. Figure 3 shows a voltage versus time diagram for a typical prior art RF-ID system. The power signal 44 of length t_2 which is the amount of time it takes to power up the furthest transponder 48 in a given RF-ID system, is transmitted and the voltage versus time diagrams for the closest 46 and the furthest 48 transponders are shown underneath. The closest transponder 46 stores V_1 amount of voltage, which is the amount of voltage required by the transponder to return a response, by time t_1 which is a very small percentage of the duration of the interrogation signal. Therefore, from t_1 to t_2 , while the furthest transponder 48 is still charging up to the required voltage V_1 and waiting for the end of the power burst signal, the closest transponder 46 is exposed to the same pulse and may heat up while it dissipates the excess energy of the interrogation signal. The excess energy being dissipated as heat by the close transponder 46 is indicated in the shaded region of the close transponders 46 voltage versus time diagram. There is little to no excess energy to be dissipated by the far transponder 48, as seen in its voltage versus time diagram, as transponder 48

requires all the energy absorbed to perform the temperature measurement, not impaired by heating-up effects, and transmit the transponder response signal.

[0023] However, in a preferred embodiment according to the invention, Figure 4 shows how varying the length of the interrogation pulse can charge-up transponders having a discharge function, located at different distances from the interrogator, to the same required voltage V_1 , without the transponders having to dissipate extra interrogation signal as heat. For example, Transponder 1 is located just a short distance from the interrogator, therefore requiring only the minimum interrogation pulse duration t_1 to achieve the required voltage V_1 to transmit a response signal. Therefore, Transponder 1 receives the interrogation pulse of duration t_1 , detects a decrease in the power level of the interrogation pulse and a voltage level V_1 , representative of a predetermined amount of power received from the interrogation pulse signal, takes a temperature measurement and transmits a response signal. As shown in Figure 4, Transponder 1 does not receive any excess interrogation signal which it must dissipate as heat. In a preferred embodiment of the invention, after sending a response signal, Transponder 1 is inactivated for a predetermined amount of time to allow the rest of the Transponders within a given interrogation range to respond. Therefore when the interrogator then transmits an interrogation pulse of duration t_2 , Transponder 1 does receive the interrogation pulse but is inactivated and does not respond thus interfere with Transponder 2 signal. Instead, Transponder 2 receives the interrogation pulse of duration t_2 , takes a temperature measurement and transmits a response signal under the same conditions as Transponder 1. Because interrogator 9 is transmitting successively longer duration interrogation pulses, instead of the maximum required duration pulses which would charge up the furthest transponder, Transponder 1, 2 and 3 are activated.

[0024] Although the transponders are receiving much closer to the exact amount of energy necessary to respond, there may still be some excess interrogation energy to dissipate, but just not nearly as much excess, especially for the transponders close to the interrogator. In a preferred embodiment according to the invention, transponder 25 performs temperature sensor functions via circuit element 38, and circuit element 38 also provides corrected temperature measurements which are corrected by an over-voltage compensating logic circuit, also a part of circuit element 38. Zener diode 34 and current sensor resistor 36 together form a current sensing over-voltage protection circuit. The value of zener diode 34 is chosen such that it will conduct when a higher voltage level exists than that representing the predetermined amount of power required to transmit a transponders response signal has been received from the interrogation signal. In other words, the conduction of the zener diode 34 signifies an over-voltage condition. Upon conduction of zener diode 34 and detection of such con-

duction by the current sensing element 36, a signal is transmitted from the current sensing element 36 to the temperature measurement compensating logic circuit of circuit element 38. The temperature measurement compensating logic circuit 38 receives a current level from the current sensing element 36 and combines this information with the amount of time elapsed from the start of current flow, then adjusts the temperature measurement accordingly, thereby compensating for the heat being generated by the excess energy of the interrogation pulse. Once the temperature measurement has been adjusted, the transponder response signal generator of circuit element 38 then transmits a response signal via antenna 26 back to the interrogator of Figure 1, wherein in one preferred embodiment according to the invention, comprises an identification code and a heat compensated temperature measurement.

[0025] In another preferred embodiment according to the invention, instead of compensating for the inaccuracy of the temperature measurement, the temperature measurement is performed before the transponder has time to heat up. In other words, before the termination of the interrogation pulse, for example, in the first millisecond that a voltage level V_1 , representative of a predetermined amount of power received from the interrogation pulse signal is detected, take the temperature measurement and then store the temperature measurement. After the transponder then detects a decrease in the power level of the interrogation signal, retrieve the temperature measurement and transmit the response signal back to the interrogator.

[0026] Another illustration of a preferred embodiment according to the invention comprising the interrogator 9 of Figure 1 and the Transponders 1, 2 and 3, which have a discharge function, of Figure 4, is illustrated in Figure 5. Interrogator 9 transmits a first minimum duration interrogation pulse of 5 msec in duration. Transponder 1 closest to the interrogator 9 charges up to the required voltage V_1 with the first interrogation pulse and sends a response signal in return. After Transponder 1 transmits a response signal back to the interrogator 9, in a preferred embodiment, Transponder 1 is inactive to transmit another response signal for the predetermined amount of time that it takes for the remainder of the transponders in the interrogation range to respond. Therefore, when the interrogator 9 sends a second pulse of 5 msec, the same duration as the first pulse, the receiver 20 of the interrogator does not detect a response signal and the duration of the next interrogation pulse is increased via the Pulse Width Control Circuit 24. In the embodiment shown in Figure 5, the increase is shown to be double the original pulse width.

[0027] Transponders 2 and 3 are further from the interrogator and charge up partially from the first and second 5 msec interrogation pulses, but do not acquire the V_1 volts required to return a response signal. Therefore, while Transponder 1, having received adequate energy from interrogation pulse of duration t_1 to respond, is

transmitting the response signal, Transponders 2 and 3 are discharging the amount of energy received from the interrogation pulse of duration t_1 . Upon transmission of the interrogation pulse of 10 msec duration, Transponder 2 is charged up to a voltage of V_1 , initiating a response signal, and subsequently inactivating Transponder 2. Again, the interrogator 9 transmits an interrogation pulse of 10 msec duration, and the receiver 20 of the interrogator does not detect a response signal and, in the embodiment shown, the Pulse Width Control Circuit 24 doubles the duration of the next interrogation pulse to 20 msec. Transponder 3 is the furthest of the transponders from the interrogator 9, thus none of the first four interrogation pulses were of sufficient duration to charge Transponder 3 to the required voltage V_1 . However, transmission of the interrogation pulse of 20 msec duration charged Transponder 3 to the voltage V_1 , initiating a response signal, and subsequently inactivating Transponder 3.

[0028] Although Figures 4 and 5 show a preferred embodiment according to the invention relative to transponders which have discharge functions, Figure 6 shows a preferred embodiment of the invention relative to transponders which have no discharge function. The advantage of using transponders with no discharge function, is that the interrogation signal duration does not have to be increased to reach further and further transponders. In addition, the transponders after receiving any energy from an interrogation signal at all, retain a substantial amount of that energy, and add any new energy received from other interrogation pulses to that existing amount of energy. For example, Transponder 60 receives some energy from the first 5 msec, minimum duration, interrogation pulse, and substantially retains that energy. Upon reception of the second 5 msec duration interrogation pulse, Transponder 60 has acquired V_1 volts of interrogation energy and is enabled to transmit a response signal. Transponder 62, which is further from the interrogator than Transponder 60, receives some energy from the first two 5 msec interrogation pulses, but because it is further from the interrogator than Transponder 60, Transponder 62 does not receive as much energy. However, the energy that Transponder 62 has received is retained and upon transmission of a third, 5 msec interrogation pulse, Transponder 62 also acquires V_1 volts and transmits a response signal. Transponder 64, which is the furthest transponder from the interrogator, also receives and retains energy from the first three, 5 msec interrogation pulses and requires two more, 5 msec interrogation pulses before it has received the necessary V_1 volts necessary to transmit a response signal.

[0029] Although Figure 6 shows that transponders with no discharge function, located at different distances from the interrogator 9, can be charged with a series of short, like duration interrogation pulses, the same transponders could be charged with a series of successively longer duration interrogation pulses, as shown in Figure

7. In this way, the interrogation process may be expedited by reaching more transponders simultaneously. Caution may be desired in the use of this interrogation method with transponders which have no discharge function because the benefits of increased range may be offset by the amount of detrimental overages incurred in many of the transponders reached.

[0030] It is to be understood that doubling the duration of the interrogation pulse is one perturbation of many possible variations. For example, the pulse duration could be increased up to the 100 % represented by doubling the duration. Actually the increase could be even greater than 100%. As a more complicated example, there is oftentimes a given gaussian or bell shaped distribution of transponders in a given interrogation range. Therefore, instead of the interrogation pulses having double the duration or some other percentage increase, upon the absence of the response signal, the interrogator could have a circuit which would calculate the probability of a transponder falling within a certain range of the interrogator, and then calculate the required interrogation pulse duration to reach that transponder. Or, another alternative would be when sending an interrogation pulse which will potentially power-up many transponders, instead of calculating a specific interrogation pulse duration, increase the duration of the interrogation pulse in much smaller steps. This method would be similar to the way that digital transformations of analog data are done. When an analog signal is in a maximum, where there are many data points located in a small area, the digital steps are made very small to increase the accuracy of the measurement. In the same way, the power time control circuit 24 of the interrogator, could, when in the vicinity of a distribution maximum, make much smaller incremental changes in the duration of the interrogation pulse.

[0031] Furthermore, if the transponders do not have a discharge function and are located beyond the maximum in the distribution of transponders, chances are that they are very close to having the required voltage V_1 necessary to send a response signal. Therefore, a decrease in the duration of the interrogation pulse may be necessary to charge-up the transponder without the risk of incurring a detrimental overage.

[0032] Figure 8 shows that in Automobile Vehicle Identification (AVI) applications involving high speed vehicles, the same types of over-voltage problems exist that are shown in the prior art voltage versus time function shown in Figure 3. An antenna 60 embedded in the road has the main lobe and side lobe field characteristics shown in the dotted lines. This field characteristic gives rise to three reading regions designated in the main lobe by "Region B" and the side lobes by "Region A". In the main lobe "Region B", the field strength is great and so a very short power pulse of length t_1 is necessary to power up the transponder to the required voltage V_1 . However, in the side lobes "Region A", there are not as many field lines so, as shown in the graph of region "A",

the pulse is not as strong and it takes a longer pulse of length t_2 to charge-up the transponder to the required voltage V_1 . Thus, an interrogator that sends longer pulse lengths to anticipate reading a car at the front of the antenna pattern, wastes a huge percent of the interrogation pulse upon entering the center of the antenna, because the transponder is charged up to the required voltage V_1 quickly and then dissipates the greater portion of the interrogation pulse as heat. Therefore, the interrogator optimally sends longer duration pulses, for example 20 msec, when no response from a transponder is detected and the car is still approaching the antenna. However, upon detection of a transponder response signal, the interrogator transmits much shorter duration interrogation pulses, for example 5 msec, because the transponder has been charged by "Region A" of the antenna once and is now in "Region B" of the antenna. The interrogator continues to transmit short duration interrogation pulses until the interrogator does not detect a transponder response for a predetermined amount of time, signifying the departure of the transponder from the range of the interrogation antenna. Upon the absence of the response signal, the interrogator transmits longer duration pulses again.

Claims

1. An identification system comprising:
 - a transponder (25) for receiving pulses of energy and then transmitting a response signal; and
 - an interrogator (9) for transmitting a series of said interrogation pulses of energy and further including a receiver (20) for monitoring for said response signal, **characterized in that** said series of interrogation pulses of energy range from pulses having a minimum duration to pulses having successive longer duration and said interrogator receiver (20) monitors for said response signal for less duration than said transmitted interrogation pulse of minimum duration, and wherein said interrogator (9) further comprises a pulse width control circuit such that in the absence of said transponder (25) transmitting a response signal, said interrogator (9) transmits an interrogation pulse having longer duration.
2. The identification system of claim 1, **characterized in that** said interrogator (9) further comprises:
 - an oscillator (10) for generating said interrogation signal,
 - said pulse width control circuit being connected to said oscillator (10) for determining the pulse duration of said interrogation signal;
 - an antenna (18) connected to said oscillator (10) for transmitting said interrogation signal and receiving said response signal;

said receiver (20) being connected to said antenna (18) for emitting a control signal in response to the absence of said response signal; a data control circuit (22) connected to said receiver (20) for sending an activating signal to said pulse width control circuit in response to said control signal, wherein said pulse width control circuit increases the duration of said interrogation pulse in response to said activating signal.

3. The identification system of claim 1, **characterized in that** said transponder (25), subsequent to the transmission of said message, is inoperable to transmit another message for a predetermined amount of time.
4. A remote sensor system comprising an interrogator (9) for transmitting a series of pulses of energy and a transponder (25) for receiving said pulses of energy and storing said pulses of energy up to a predetermined amount of voltage, **characterized in that** said pulses range from pulses having a minimum duration to pulses having successively longer duration and subsequent to storing said pulses of energy up to a predetermined level said transponder (25) dissipates the remainder of said pulses as heat, thereby indicating an over-voltage condition, and also senses an environmental condition and transmits a response signal.
5. The remote sensor system of claim 4, **characterized in that** said transponder (25) further comprises over-voltage protection circuitry (34, 36) and compensatory logic circuitry such that in response to said over-voltage condition, said compensatory logic circuitry compensates said sensed environmental condition for said over-voltage condition.
6. The remote sensor system of claim 5, **characterized in that** said response signal comprises an identification code and said compensated environmental condition.
7. A method of interrogation in a communication system comprising an interrogator (9), which transmits an interrogation signal, and transponders (25) which receive the interrogation signal and transmit a response signal, comprising the steps of:

generating a first interrogation signal comprising a minimum duration pulse;
transmitting said minimum duration pulse;
monitoring for a response signal and in the absence of said response signal, increasing the pulse duration of said interrogation signal; and
repeating said generating, transmitting, monitoring and increasing steps until said response

signal is detected.

8. The method of claim 7, **characterized in that** said monitoring step is performed by a receiver (20) in the interrogator (9).
9. The method of claim 7, **characterized in that** said increasing step comprises the steps of transmitting a control signal from said receiver (20) to a data control circuit (22), transmitting an activating signal from said data control circuit (22) to a pulse width control circuit in response to said control signal, increasing the pulse duration via said pulse width control circuit in response to said activating signal.
10. The method of claim 7, **characterized in that** said generating step is performed by an oscillator (10) in the interrogator (9).
11. The method of claim 7, **characterized in that** said monitoring for a response signal occurs for a predetermined duration.
12. The method of claim 11, **characterized in that** said predetermined duration is of shorter duration than said minimum duration interrogation pulse.

Patentansprüche

1. Identifizierungssystem, mit :
einem Transponder (25) zum Empfangen von Energieimpulsen und zum anschließenden Senden eines Antwortsignals; und einer Abfrageeinrichtung (9) zum Senden einer Reihe der Abfrage-Energieimpulse, der ferner einen Empfänger (20) zum Überwachen der Antwortsignale enthält, **dadurch gekennzeichnet, daß** die Reihe der Abfrage-Energieimpulse von Impulsen mit minimaler Dauer bis zu Impulsen mit sukzessive längerer Dauer reicht und der Abfrageempfänger (22) das Antwortsignal während einer kürzeren Dauer als diejenige des gesendeten Abfrageimpulses mit minimaler Dauer überwacht, wobei die Abfrageeinrichtung (9) ferner eine Impulsbreiten-Steuerschaltung enthält, derart, daß bei Fehlen eines vom Transponder (25) gesendeten Antwortsignals die Abfrageeinrichtung (9) einen Abfrageimpuls mit längerer Dauer sendet.
2. Identifizierungssystem nach Anspruch 1, **dadurch gekennzeichnet, daß** die Abfrageeinrichtung (9) ferner enthält:

einen Oszillator (10) zum Erzeugen des Abfragesignals,
wobei die Impulsbreiten-Steuerschaltung mit dem Oszillator (10) verbunden ist, um die Im-

- pulsdauer des Abfragesignals zu bestimmen;
eine Antenne (18), die mit dem Oszillator (10) verbunden ist, um das Abfragesignal zu senden und das Antwortsignal zu empfangen;
wobei der Empfänger (20) mit der Antenne (18) verbunden ist, um als Antwort auf das Fehlen des Antwortsignals ein Steuersignal zu senden;
eine Datensteuereinheit (22), die mit dem Empfänger (20) verbunden ist, um als Antwort auf das Steuersignal ein Aktivierungssignal an die Impulsbreiten-Steuerschaltung zu schicken, die die Dauer des Abfrageimpulses als Antwort auf das Aktivierungssignal erhöht.
3. Identifizierungssystem nach Anspruch 1, **dadurch gekennzeichnet, daß** der Transponder (25) im Anschluß an das Senden der Nachricht während einer vorgegebenen Zeitdauer keine weitere Nachricht senden kann.
4. Fernsensorsystem, das eine Abfrageeinrichtung (9) zum Senden einer Reihe von Energieimpulsen und einen Transponder (25) zum Empfangen der Energieimpulse und zum Speichern der Energieimpulse bis zu einer vorgegebenen Spannung enthält, **dadurch gekennzeichnet, daß** die Impulse von Impulsen mit minimaler Dauer bis zu Impulsen mit sukzessive längerer Dauer reichen und daß der Transponder (25) im Anschluß an das Speichern der Energieimpulse bis zu einem vorgegebenen Pegel die restlichen Impulse als Wärme abführt, wodurch ein Überspannungszustand angezeigt wird, und außerdem eine Umgebungsbedingung erfaßt sowie ein Antwortsignal sendet.
5. Fernsensorsystem nach Anspruch 4, **dadurch gekennzeichnet, daß** der Transponder (25) ferner eine Überspannungsschutz-Schaltungsanordnung (34, 36) und eine Kompensationslogik-Schaltungsanordnung enthält, derart, daß als Antwort auf den Überspannungszustand die Kompensationslogik-Schaltungsanordnung die erfaßte Umgebungsbedingung für den Überspannungszustand erfaßt.
6. Fernsensorsystem nach Anspruch 5, **dadurch gekennzeichnet, daß** das Antwortsignal einen Identifizierungscode und die kompensierte Umgebungsbedingung enthält.
7. Abfrageverfahren in einem Kommunikationssystem, das eine Abfrageeinrichtung (9), die ein Abfragesignal sendet, und Transponder (25), die das Abfragesignal empfangen und ein Antwortsignal senden, enthält, mit den folgenden Schritten:
- Erzeugen eines ersten Abfragesignals, das einen Impuls mit minimaler Dauer enthält;
- Senden des Impulses mit minimaler Dauer;
Überwachen eines Antwortsignals und, wenn das Antwortsignal nicht vorhanden ist, Erhöhen der Impulsdauer des Abfragesignals; und
Wiederholen der Erzeugungs-, Sende-, Überwachungs- und Erhöhungsschritte, bis das Antwortsignal erfaßt wird.
8. Verfahren nach Anspruch 7, **dadurch gekennzeichnet, daß** der Überwachungsschritt durch einen Empfänger (20) in der Abfrageeinrichtung (9) ausgeführt wird.
9. Verfahren nach Anspruch 7, **dadurch gekennzeichnet, daß** der Erhöhungsschritt die folgenden Schritte enthält: Senden eines Steuersignals vom Empfänger (20) an eine Datensteuereinheit (22), Senden eines Aktivierungssignals von der Datensteuereinheit (22) an eine Impulsbreiten-Steuerschaltung als Antwort auf das Steuersignal und Erhöhen der Impulsdauer mittels der Impulsbreiten-Steuerschaltung als Antwort auf das Aktivierungssignal.
10. Verfahren nach Anspruch 7, **dadurch gekennzeichnet, daß** der Erzeugungsschritt durch einen Oszillator (10) in der Abfrageeinrichtung (9) ausgeführt wird.
11. Verfahren nach Anspruch 7, **dadurch gekennzeichnet, daß** die Überwachung eines Antwortsignals während einer vorgegebenen Dauer erfolgt.
12. Verfahren nach Anspruch 11, **dadurch gekennzeichnet, daß** die vorgegebene Dauer kürzer als diejenige des Abfrageimpulses mit minimaler Dauer ist.
- 40 **Revendications**
1. Système d'identification comprenant :
- un répondeur (25) pour recevoir des impulsions d'énergie et émettre alors un signal de réponse ; et un interrogateur (9) pour émettre une série desdites impulsions d'interrogation d'énergie et comprenant en outre un récepteur (20) pour surveiller ledit signal de réponse, caractérisé en ce que ladite série d'impulsions d'interrogation d'énergie s'étend depuis des impulsions ayant une durée minimale à des impulsions ayant des durées successives plus longues et que ledit récepteur (20) d'interrogateur surveille ledit signal de réponse pendant une durée inférieure à ladite impulsion émise d'interrogation de durée minimale, et dans lequel ledit interrogateur (9) comprend en outre un circuit de commande de largeur d'impulsion, de sorte qu'en l'absence d'émission par ledit répondeur (25) d'un

signal de réponse, ledit interrogateur (9) émet une impulsion d'interrogation ayant une durée plus longue.

2. Système d'identification selon la revendication 1, caractérisé en ce que ledit interrogateur (9) comprend en outre :

un oscillateur (10) pour produire ledit signal d'interrogation, ledit circuit de commande de largeur d'impulsion étant relié audit oscillateur (10) pour déterminer la durée d'impulsion dudit signal d'interrogation ;
une antenne (18) reliée audit oscillateur (10) pour émettre ledit signal d'interrogation et recevoir ledit signal de réponse ;
ledit récepteur (20) étant relié à ladite antenne (18) pour émettre un signal de commande en réponse à l'absence dudit signal de réponse ;
un circuit (22) de commande de données relié audit récepteur (20) pour envoyer un signal d'activation audit circuit de commande de largeur d'impulsion en réponse audit signal de commande, dans lequel ledit circuit de commande de largeur d'impulsion augmente la durée de ladite impulsion d'interrogation en réponse audit signal d'activation.

3. Système d'identification selon la revendication 1, caractérisé en ce que ledit répondeur (25), après l'émission dudit message, est empêché d'émettre un autre message pendant un intervalle prédéterminé de temps.

4. Système de capteurs éloignés comprenant un interrogateur (9) pour émettre une série d'impulsions d'énergie et un répondeur (25) pour recevoir lesdites impulsions d'énergie et stocker lesdites impulsions d'énergie jusqu'à une valeur prédéterminée de tension, caractérisé en ce que lesdites impulsions s'étendent depuis des impulsions ayant une durée minimale jusqu'à des impulsions ayant des durées successivement plus longues et, après le stockage desdites impulsions d'énergie jusqu'à une valeur prédéterminée de tension, ledit répondeur d'identification (25) dissipe le reste desdites impulsions sous forme de chaleur, indiquant ainsi une condition de surtension, et détecte aussi une condition d'environnement et émet un signal de réponse.

5. Système de capteurs éloignés selon la revendication 4, caractérisé en ce que ledit répondeur d'identification (25) comprend en outre un circuit (34, 36) de protection anti-surtension et un circuit logique compensatoire, de sorte qu'en réponse à ladite condition de surtension, ledit circuit logique compensa-

toire compense ladite condition détectée d'environnement pour ladite condition de surtension.

6. Système de capteurs éloignés selon la revendication 5, caractérisé en ce que ledit signal de réponse comprend un code d'identification et ladite condition compensée d'environnement.

7. Procédé d'interrogation dans un système de communication comprenant un interrogateur (9), qui émet un signal d'interrogation, et des répondeurs (25) qui reçoivent le signal d'interrogation et émettent un signal de réponse, comprenant les étapes consistant à :

produire un premier signal d'interrogation comprenant une impulsion de durée minimale ;
émettre ladite impulsion de durée minimale ;
surveiller un signal de réponse et, en l'absence dudit signal de réponse, augmenter la durée d'impulsion dudit signal d'interrogation ; et
répéter lesdites étapes de génération, émission, surveillance et augmentation jusqu'à ce que ledit signal de réponse soit détecté.

8. Procédé selon la revendication 7, caractérisé en ce que ladite étape de surveillance est exécutée par un récepteur (20) dans l'interrogateur (9).

9. Procédé selon la revendication 7, caractérisé en ce que ladite étape d'augmentation comprend les étapes consistant à envoyer un signal de commande depuis ledit récepteur (20) à un circuit (22) de commande de données, émettre un signal d'activation depuis ledit circuit (22) de commande de données à un circuit de commande de largeur d'impulsion en réponse audit signal de commande, et augmenter la durée d'impulsion au moyen dudit circuit de commande de largeur d'impulsion en réponse audit signal d'activation.

10. Procédé selon la revendication 7, caractérisé en ce que ladite étape de génération est exécutée par un oscillateur (10) dans l'interrogateur.

11. Procédé selon la revendication 7, caractérisé en ce que ladite surveillance d'un signal de réponse a lieu pendant une durée prédéterminée.

12. Procédé selon la revendication 7, caractérisé en ce que ladite durée prédéterminée a une valeur plus courte que ladite impulsion d'interrogation de durée minimale.
